

CHAPTER 4

SOLUTIONS TO PROBLEMS

4.2 (i) and (iii) generally cause the t statistics not to have a t distribution under H_0 . Homoskedasticity is one of the CLM assumptions. An important omitted variable violates Assumption MLR.3. The CLM assumptions contain no mention of the sample correlations among independent variables, except to rule out the case where the correlation is one.

4.3 (i) While the standard error on $hrsemp$ has not changed, the magnitude of the coefficient has increased by half. The t statistic on $hrsemp$ has gone from about -1.47 to -2.21 , so now the coefficient is statistically less than zero at the 5% level. (From Table G.2 the 5% critical value with 40 df is -1.684 . The 1% critical value is -2.423 , so the p -value is between .01 and .05.)

(ii) If we add and subtract $\beta_2 \log(employ)$ from the right-hand-side and collect terms, we have

$$\begin{aligned} \log(scrap) &= \beta_0 + \beta_1 hrsemp + [\beta_2 \log(sales) - \beta_2 \log(employ)] \\ &\quad + [\beta_2 \log(employ) + \beta_3 \log(employ)] + u \\ &= \beta_0 + \beta_1 hrsemp + \beta_2 \log(sales/employ) \\ &\quad + (\beta_2 + \beta_3) \log(employ) + u, \end{aligned}$$

where the second equality follows from the fact that $\log(sales/employ) = \log(sales) - \log(employ)$. Defining $\theta_3 \equiv \beta_2 + \beta_3$ gives the result.

(iii) No. We are interested in the coefficient on $\log(employ)$, which has a t statistic of .2, which is very small. Therefore, we conclude that the size of the firm, as measured by employees, does not matter, once we control for training *and* sales per employee (in a logarithmic functional form).

(iv) The null hypothesis in the model from part (ii) is $H_0: \beta_2 = -1$. The t statistic is $[-.951 - (-1)]/.37 = (1 - .951)/.37 \approx .132$; this is very small, and we fail to reject whether we specify a one- or two-sided alternative.

4.4 (i) In columns (2) and (3), the coefficient on $profmarg$ is actually negative, although its t statistic is only about -1 . It appears that, once firm sales and market value have been controlled for, profit margin has no effect on CEO salary.

(ii) We use column (3), which controls for the most factors affecting salary. The t statistic on $\log(mktval)$ is about 2.05, which is just significant at the 5% level against a two-sided alternative.

(We can use the standard normal critical value, 1.96.) So $\log(mktval)$ is statistically significant. Because the coefficient is an elasticity, a ceteris paribus 10% increase in market value is predicted to increase *salary* by 1%. This is not a huge effect, but it is not negligible, either.

(iii) These variables are individually significant at low significance levels, with $t_{ceoten} \approx 3.11$ and $t_{comten} \approx -2.79$. Other factors fixed, another year as CEO with the company increases salary by about 1.71%. On the other hand, another year with the company, but not as CEO, lowers salary by about .92%. This second finding at first seems surprising, but could be related to the “superstar” effect: firms that hire CEOs from outside the company often go after a small pool of highly regarded candidates, and salaries of these people are bid up. More non-CEO years with a company makes it less likely the person was hired as an outside superstar.

4.7 (i) $.412 \pm 1.96(.094)$, or about .228 to .596.

(ii) No, because the value .4 is well inside the 95% CI.

(iii) Yes, because 1 is well outside the 95% CI.

4.8 (i) With $df = 706 - 4 = 702$, we use the standard normal critical value ($df = \infty$ in Table G.2), which is 1.96 for a two-tailed test at the 5% level. Now $t_{educ} = -11.13/5.88 \approx -1.89$, so $|t_{educ}| = 1.89 < 1.96$, and we fail to reject $H_0: \beta_{educ} = 0$ at the 5% level. Also, $t_{age} \approx 1.52$, so *age* is also statistically insignificant at the 5% level.

(ii) We need to compute the *R*-squared form of the *F* statistic for joint significance. But $F = [(.113 - .103)/(1 - .113)](702/2) \approx 3.96$. The 5% critical value in the $F_{2,702}$ distribution can be obtained from Table G.3b with denominator $df = \infty$: $cv = 3.00$. Therefore, *educ* and *age* are jointly significant at the 5% level ($3.96 > 3.00$). In fact, the *p*-value is about .019, and so *educ* and *age* are jointly significant at the 2% level.

(iii) Not really. These variables are jointly significant, but including them only changes the coefficient on *totwrk* from $-.151$ to $-.148$.

(iv) The standard *t* and *F* statistics that we used assume homoskedasticity, in addition to the other CLM assumptions. If there is heteroskedasticity in the equation, the tests are no longer valid.

4.11 (i) Holding *profmarg* fixed, $\widehat{\Delta rdintens} = .321 \Delta \log(sales) = (.321/100)[100 \cdot \Delta \log(sales)] \approx .00321(\% \Delta sales)$. Therefore, if $\% \Delta sales = 10$, $\widehat{\Delta rdintens} \approx .032$, or only about 3/100 of a percentage point. For such a large percentage increase in sales, this seems like a practically small effect.

(ii) $H_0: \beta_1 = 0$ versus $H_1: \beta_1 > 0$, where β_1 is the population slope on $\log(sales)$. The *t* statistic is $.321/.216 \approx 1.486$. The 5% critical value for a one-tailed test, with $df = 32 - 3 = 29$, is obtained from Table G.2 as 1.699; so we cannot reject H_0 at the 5% level. But the 10% critical

value is 1.311; since the t statistic is above this value, we reject H_0 in favor of H_1 at the 10% level.

(iii) Not really. Its t statistic is only 1.087, which is well below even the 10% critical value for a one-tailed test.

SOLUTIONS TO COMPUTER EXERCISES

C4.1 (i) Holding other factors fixed,

$$\begin{aligned}\Delta voteA &= \beta_1 \Delta \log(expendA) = (\beta_1 / 100)[100 \cdot \Delta \log(expendA)] \\ &\approx (\beta_1 / 100)(\% \Delta expendA),\end{aligned}$$

where we use the fact that $100 \cdot \Delta \log(expendA) \approx \% \Delta expendA$. So $\beta_1 / 100$ is the (ceteris paribus) percentage point change in $voteA$ when $expendA$ increases by one percent.

(ii) The null hypothesis is $H_0: \beta_2 = -\beta_1$, which means a $z\%$ increase in expenditure by A and a $z\%$ increase in expenditure by B leaves $voteA$ unchanged. We can equivalently write $H_0: \beta_1 + \beta_2 = 0$.

(iii) The estimated equation (with standard errors in parentheses below estimates) is

$$\widehat{voteA} = 45.08 + 6.083 \log(expendA) - 6.615 \log(expendB) + .152 prtystA$$

$$(3.93) \quad (0.382) \quad (0.379) \quad (.062)$$

$$n = 173, \quad R^2 = .793.$$

The coefficient on $\log(expendA)$ is very significant (t statistic ≈ 15.92), as is the coefficient on $\log(expendB)$ (t statistic ≈ -17.45). The estimates imply that a 10% ceteris paribus increase in spending by candidate A increases the predicted share of the vote going to A by about .61 percentage points. [Recall that, holding other factors fixed, $\Delta \widehat{voteA} \approx (6.083/100)\% \Delta expendA$.] Similarly, a 10% ceteris paribus increase in spending by B reduces \widehat{voteA} by about .66 percentage points. These effects certainly cannot be ignored.

While the coefficients on $\log(expendA)$ and $\log(expendB)$ are of similar magnitudes (and opposite in sign, as we expect), we do not have the standard error of $\hat{\beta}_1 + \hat{\beta}_2$, which is what we would need to test the hypothesis from part (ii).

(iv) Write $\theta_1 = \beta_1 + \beta_2$, or $\beta_1 = \theta_1 - \beta_2$. Plugging this into the original equation, and rearranging, gives

$$\widehat{voteA} = \beta_0 + \theta_1 \log(expendA) + \beta_2 [\log(expendB) - \log(expendA)] + \beta_3 prtystA + u,$$

When we estimate this equation we obtain $\hat{\theta}_1 \approx -.532$ and $se(\hat{\theta}_1) \approx .533$. The t statistic for the hypothesis in part (ii) is $-.532/.533 \approx -1$. Therefore, we fail to reject $H_0: \beta_2 = -\beta_1$.

C4.3 (i) The estimated model is

$$\widehat{\log(\text{price})} = 11.67 + .000379 \text{ sqrft} + .0289 \text{ bdrms}$$

$$(0.10) \quad (.000043) \quad (.0296)$$

$$n = 88, R^2 = .588.$$

Therefore, $\hat{\theta}_1 = 150(.000379) + .0289 = .0858$, which means that an additional 150 square foot bedroom increases the predicted price by about 8.6%.

(ii) $\beta_2 = \theta_1 - 150\beta_1$, and so

$$\begin{aligned} \log(\text{price}) &= \beta_0 + \beta_1 \text{ sqrft} + (\theta_1 - 150\beta_1) \text{ bdrms} + u \\ &= \beta_0 + \beta_1 (\text{ sqrft} - 150 \text{ bdrms}) + \theta_1 \text{ bdrms} + u. \end{aligned}$$

(iii) From part (ii), we run the regression

$$\log(\text{price}) \text{ on } (\text{ sqrft} - 150 \text{ bdrms}), \text{ bdrms},$$

and obtain the standard error on *bdrms*. We already know that $\hat{\theta}_1 = .0858$; now we also get $\text{se}(\hat{\theta}_1) = .0268$. The 95% confidence interval reported by my software package is .0326 to .1390 (or about 3.3% to 13.9%).

C4.5 (i) If we drop *rbisy* the estimated equation becomes

$$\begin{aligned} \widehat{\log(\text{salary})} &= 11.02 + .0677 \text{ years} + .0158 \text{ gamesyr} \\ &\quad (0.27) \quad (.0121) \quad (.0016) \\ &\quad + .0014 \text{ bav} + .0359 \text{ hrunsyr} \\ &\quad (.0011) \quad (.0072) \end{aligned}$$

$$n = 353, R^2 = .625.$$

Now *hrunsyr* is very statistically significant (t statistic ≈ 4.99), and its coefficient has increased by about two and one-half times.

(ii) The equation with *runsy*, *fldperc*, and *sbasesyr* added is

$$\begin{aligned} \widehat{\log(\text{salary})} = & 10.41 + .0700 \text{ years} + .0079 \text{ gamesyr} \\ & (2.00) \quad (.0120) \quad (.0027) \\ & + .00053 \text{ bavg} + .0232 \text{ hrunsyr} \\ & \quad (.00110) \quad (.0086) \\ & + .0174 \text{ runsyr} + .0010 \text{ fldperc} - .0064 \text{ sbasesyr} \\ & \quad (.0051) \quad (.0020) \quad (.0052) \end{aligned}$$

$$n = 353, R^2 = .639.$$

Of the three additional independent variables, only *runsyr* is statistically significant (t statistic = $.0174/.0051 \approx 3.41$). The estimate implies that one more run per year, other factors fixed, increases predicted salary by about 1.74%, a substantial increase. The stolen bases variable even has the “wrong” sign with a t statistic of about -1.23 , while *fldperc* has a t statistic of only $.5$. Most major league baseball players are pretty good fielders; in fact, the smallest *fldperc* is 800 (which means $.800$). With relatively little variation in *fldperc*, it is perhaps not surprising that its effect is hard to estimate.

(iii) From their t statistics, *bavg*, *fldperc*, and *sbasesyr* are individually insignificant. The F statistic for their joint significance (with 3 and 345 df) is about $.69$ with p -value $\approx .56$. Therefore, these variables are jointly very insignificant.

C4.7 (i) The minimum value is 0, the maximum is 99, and the average is about 56.16.

(ii) When *phsrank* is added to (4.26), we get the following:

$$\begin{aligned} \widehat{\log(\text{wage})} = & 1.459 - .0093 \text{ jc} + .0755 \text{ totcoll} + .0049 \text{ exper} + .00030 \text{ phsrank} \\ & (0.024) \quad (.0070) \quad (.0026) \quad (.0002) \quad (.00024) \end{aligned}$$

$$n = 6,763, R^2 = .223$$

So *phsrank* has a t statistic equal to only 1.25; it is not statistically significant. If we increase *phsrank* by 10, $\log(\text{wage})$ is predicted to increase by $(.0003)10 = .003$. This implies a .3% increase in *wage*, which seems a modest increase given a 10 percentage point increase in *phsrank*. (However, the sample standard deviation of *phsrank* is about 24.)

(iii) Adding *phsrank* makes the t statistic on *jc* even smaller in absolute value, about 1.33, but the coefficient magnitude is similar to (4.26). Therefore, the base point remains unchanged: the return to a junior college is estimated to be somewhat smaller, but the difference is not significant and standard significant levels.

(iv) The variable *id* is just a worker identification number, which should be randomly assigned (at least roughly). Therefore, *id* should not be correlated with any variable in the regression equation. It should be insignificant when added to (4.17) or (4.26). In fact, its t statistic is about $.54$.

C4.9 (i) The results from the OLS regression, with standard errors in parentheses, are

$$\widehat{\log(psoda)} = -1.46 + .073 prpblck + .137 \log(income) + .380 prppov$$

$$(0.29) \quad (.031) \quad (.027) \quad (.133)$$

$$n = 401, R^2 = .087$$

The p -value for testing $H_0: \beta_1 = 0$ against the two-sided alternative is about .018, so that we reject H_0 at the 5% level but not at the 1% level.

(ii) The correlation is about $-.84$, indicating a strong degree of multicollinearity. Yet each coefficient is very statistically significant: the t statistic for $\hat{\beta}_{\log(income)}$ is about 5.1 and that for $\hat{\beta}_{prppov}$ is about 2.86 (two-sided p -value = .004).

(iii) The OLS regression results when $\log(hseval)$ is added are

$$\widehat{\log(psoda)} = -.84 + .098 prpblck - .053 \log(income)$$

$$(.29) \quad (.029) \quad (.038)$$

$$+ .052 prppov + .121 \log(hseval)$$

$$(.134) \quad (.018)$$

$$n = 401, R^2 = .184$$

The coefficient on $\log(hseval)$ is an elasticity: a one percent increase in housing value, holding the other variables fixed, increases the predicted price by about .12 percent. The two-sided p -value is zero to three decimal places.

(iv) Adding $\log(hseval)$ makes $\log(income)$ and $prppov$ individually insignificant (at even the 15% significance level against a two-sided alternative for $\log(income)$, and $prppov$ is does not have a t statistic even close to one in absolute value). Nevertheless, they are jointly significant at the 5% level because the outcome of the $F_{2,396}$ statistic is about 3.52 with p -value = .030. All of the control variables – $\log(income)$, $prppov$, and $\log(hseval)$ – are highly correlated, so it is not surprising that some are individually insignificant.

(v) Because the regression in (iii) contains the most controls, $\log(hseval)$ is individually significant, and $\log(income)$ and $prppov$ are jointly significant, (iii) seems the most reliable. It holds fixed three measure of income and affluence. Therefore, a reasonable estimate is that if the proportion of blacks increases by .10, $psoda$ is estimated to increase by 1%, other factors held fixed.
